## 1. Introduction

Some of today’s most important environmental concerns relate to the composition of the atmosphere. The increasing concentration of the greenhouse gases and the cooling effect of aerosol are prominent drivers of a changing climate, but the extent of their impact is often still uncertain.

At the Earth’s surface, aerosols, ozone and other reactive gases such as nitrogen dioxide determine the quality of the air around us, affecting human health and life expectancy, the health of ecosystems and the fabric of the built environment. Ozone distributions in the stratosphere influence the amount of ultra-violet radiation reaching the surface. Dust, sand, smoke and volcanic aerosols affect the safe operation of transport systems and the availability of power from

solar generation, the formation of clouds and rainfall, and the remote sensing by satellite of land, ocean and atmosphere.

To address these environmental concerns there is a need for data and processed information. The Copernicus Atmosphere Monitoring Service (CAMS) has been developed to meet these needs, aiming at supporting policymakers, business and citizens with enhanced atmospheric environmental information.

The Copernicus Atmosphere Monitoring Service (CAMS, [atmosphere.copernicus.eu/](http://atmosphere.copernicus.eu/)) is establishing the core global and regional atmospheric environmental service delivered as a component of Europe's Copernicus programme.

## 2. Study Area, Data & Materials

{Introduction}

### 2.1. Pollutants

#### 2.1.1. Surface Ozone ( $O_3$ )

Ozone ( $O_3$ ) in the troposphere (the lowermost part of the atmosphere, from the surface to 6-15 km height depending on the latitude) is highly relevant for the Earth's climate, ecosystems, and human health. Tropospheric ozone is the third largest contributor to greenhouse radiative forcing after carbon dioxide and methane (Forster et al., 2007). It is part of the Earth's shield against ultraviolet radiation, particularly when there is stratospheric ozone depletion (Sabziparvar et al., 1998).

Ozone plays a crucial role in tropospheric chemistry as the main precursor for the OH radical which determines the oxidation capacity of the troposphere (Seinfeld and Pandis, 2006). It is a toxic air pollutant affecting human health (Bell et al., 2006) and agriculture (Royal Society 2008). Furthermore, through plant damage, it impedes the uptake of carbon into the biosphere (Sitch et al., 2007).

Accurate long-term measurements of ozone in the troposphere, including near the earth surface in unpolluted and polluted environments, are needed in order to assess the impacts of tropospheric ozone on the earth system, human health and ecosystems, and to detect changes in the atmospheric composition which could aggravate or reduce these impacts because of changing ozone precursor emissions or climate change.

#### 2.1.2. $NO_x$ : Nitric Oxide (NO) + Nitrogen Dioxide ( $NO_2$ )

$NO_x$  is a generic term for the mono-nitrogen oxides (Mollenhauer and Tschöke, 2010; Omidvarborna et al., 2015), nitric oxide (NO) and nitrogen dioxide ( $NO_2$ ). They are produced from the reaction among nitrogen, oxygen and even hydrocarbons (during combustion), especially at high temperatures (Omidvarborna et al., 2015; Annamalai, 2007).

## **2.2. Study Areas**

### **2.2.1. Global**

### **2.2.2. European-scale**

The regional forecasting service provides daily 4-day forecasts of the main air quality species and analyses of the day before, from 7 state-of-the-art atmospheric chemistry models and from the median ensemble calculated from the 7 model forecasts. The regional service also provides posteriori reanalyses using the latest validated observation dataset available for assimilation.

## **2.3. Available Files**

## **2.4. Data Access Methods**

## **3. Models**

### **3.1. Global**

### **3.2. European-scale**

The MACC-II air quality system aims at providing analyses and forecasts of the main pollutants at the regional scale over the European continent: from 25° W to 45° E and from 30 to 70° N.

Each of the seven models is run at its own horizontal and vertical resolutions, with the horizontal resolutions varying between 20 and 10km. This range of resolutions is not designed to reproduce local aspects of air pollution but to provide concentrations of pollutants at the regional scale that can then be used in particular as boundary conditions for air quality forecasts at finer resolution.

The range of the forecasts is 96h from 00:00 UTC on Day0 with hourly outputs on eight vertical levels (surface, 50, 250, 500, 1000, 2000, 3000 and 5000m). Day0 is defined as the day when the forecast is run. The forecast initial time/date is Day0 at 00:00 UTC and final time/date is Day3 at 24:00UTC. For each time step (1h), the individual model fields are interpolated on these vertical levels and on the same regular 0.1° latitude by 0.1° longitude grid over the European domain. It is from these re-gridded fields that the ensemble median and verification products are calculated.

The analysis at the surface for Day0-1 (the day before Day0) is run daily a posteriori on Day0 using the assimilation of the hourly data from the AQ monitoring stations available in Europe between 00:00 and 23:00UTC on Day0-1. Like for the forecasts, Day0 is defined as the day when the analysis is run. The analysis initial time/date is Day0-1 at 00:00 UTC and final time/date is Day0-1 at 23:00 UTC. Similarly to the forecasts, the hourly individual model fields are interpolated on the same 0.1° latitude by 0.1° longitude grid. The analyses are only produced at the surface level.

	<b>Forecast</b>	<b>Analysis</b>
<b>Altitudes</b>	Surface, 50m, 250m 500m, 1000m, 2000m 3000m, 5000m	Surface
<b>Available at</b>	6:00 UTC	09:45 UTC for the day before
<b>Species</b>	O <sub>3</sub> , NO, NO <sub>2</sub>	O <sub>3</sub> , NO, NO <sub>2</sub>
<b>Timespan</b>	0-96h, hourly	0-24h for the day before, hourly

**Table 1.** Products of CHIMERE model

### 3.2.1. CHIMERE

CHIMERE is an Eulerian chemistry-transport model able to simulate concentration fields of gaseous and aerosols species at a regional scale (Menuet et al., 2013a). The model is developed under the General Public License licence<sup>1</sup>. CHIMERE is used for analysis of pollution events, process studies, (Bessagnet et al., 2009; Beekmann and Vautard, 2010), experimental and operational forecasts (Rouil et al., 2009), regional climate studies and trends (Colette et al., 2011), among others.

CHIMERE runs over a range of spatial scale from the regional scale (several thousand kilometres) to the urban scale (100-200 Km) with resolutions from 1-2 Km to 100 Km. The model runs over the GEMS-MACC domain with a 0.1° resolution and 8 vertical levels extending from the surface up to 500 hPa, covering the whole troposphere.

CHIMERE reproduces nicely the day to day O<sub>3</sub> variation similarly at urban and rural sites with an overestimation which is higher during the winter at urban sites. CHIMERE reproduces the daily NO<sub>x</sub> variability along the year but underestimates significantly the concentration especially during the cold season.

### 3.2.2. EMEP

The EMEP/MSC-W model has been developed at the EMEP Meteorological Synthesizing Centre-West at the Norwegian Meteorological Institute. The model has been publicly available as open-source code since 2008, and a detailed description is given in Simpson et al. (2012).

One strength of the EMEP model is that its domain extends throughout the whole troposphere, thus taking accurate account of long-range transport of pollutants in the free troposphere. As the model is designed mainly for background concentrations, urban increments have not been implemented as in some other models with equally coarse resolution, leading to somewhat lower

<sup>1</sup>Official website: <http://www.lmd.polytechnique.fr/chimere/>

performance in urban and sub-urban areas. However, being one of the main research tools under the UN LRTAP (Long-range Transboundary Air Pollution) convention, the EMEP model is evaluated continuously against measurements of a large range of chemical parameters (including air concentrations, depositions, and trends) ensuring modelling capability with very good overall performance (e.g. Jonson et al., 2006; Fagerli and Aas, 2008; Genberg et al., 2013).

### **3.2.3. EURAD-IM**

EURAD-IM is an Eulerian meso-scale chemistry transport model involving advection, diffusion, chemical transformation, wet and dry deposition and sedimentation of tropospheric trace gases and aerosols (Hass et al., 1995, Memmesheimer et al., 2004). It includes 3DVar and 4DVar chemical data assimilation (Elbern et al., 2007) and is able to run in nesting mode. EURAD-IM has been applied on several recent air pollution studies (Monteiro et al., 2013; Zyryanov et al., 2012; Monteiro et al., 2012; Elbern et al., 2011; Kanakidou et al., 2011).

### **3.2.4. LOTOS-EUROS**

The 3-D chemistry-transport model LOTOS-EUROS (Schaap et al., 2008) is developed by the Dutch institutes TNO, RIVM and, more recently, KNMI. It is used for regional-scale air quality forecasts in Europe and the Netherlands (De Ruyter de Wildt et al., 2011).

The model extends up to 3.5km above sea level, with three dynamic layers and a fixed 25m thick surface layer. The lowest dynamic layer is the mixing layer, followed by two reservoir layers. The height of the mixing layer is obtained from the ECMWF meteorological input data used to drive the model.

The LOTOS-EUROS model has been designed as a model of intermediate complexity, to favour short computation times. For this, the vertical top of the operational model version is limited and covers only the boundary layer and reservoir layers (up to 3.5km); effectively, the model therefore employs only four dynamic layers. Concentrations from the free troposphere are taken from the global boundary conditions, and therefore fully incorporate the knowledge, assimilations, and validation efforts present in the global model.

In spite of the limited complexity, the model performs well in simulation of O<sub>3</sub> (Curier et al., 2012).

Apart from the relative short run-through time, the strength of the model is in the detailed description of anthropogenic emissions, given the close cooperation with the developers of the TNO-MACC emission inventory; this is for example shown by excellent simulation of boundary layer NO<sub>2</sub> (Vlemmix et al., 2015).

### **3.2.5. MATCH**

The MATCH model has been developed at SMHI over the past 20 years and is applied for emergency purposes as well as for regional-scale chemistry modelling (Langner et al., 1998; Robertson et al., 1999).

The strength of the MATCH model is that it spans vertically the troposphere and makes use of the same vertical layers as provided from the IFS model up to 300hPa. This means about 50 layers in the vertical and the lowest one just 20m thick and about 15 in the boundary layer. Using the same vertical resolution as the IFS model is an advantage because no vertical interpolation is required. Nevertheless, since the MATCH model has been developed mainly using HIRLAM (High-Resolution Limited Area Model) data with a coarser vertical resolution, the use of the high-resolution vertical levels from IFS may lead to less accurate chemistry forecasts compared to the HIRLAM version

### 3.2.6. MOCAGE

The MOCAGE model (Josse et al., 2004; Dufour et al., 2004) has been developed at Météo-France since 2000. Its assimilation system has been developed jointly with CERFACS. This model and its assimilation system have been successfully used for tropospheric and stratospheric research (e.g. Bousserez et al., 2007; Barré et al., 2013, 2014; Lacressonnière et al., 2014) and also for operational purposes (Rouil et al., 2009).

The strength of MOCAGE is that it simulates the air composition of the whole troposphere and lower stratosphere. Thus, it provides a full representation of transport processes, in particular boundary layer–troposphere and troposphere–stratosphere exchanges, and the time evolution of stratospheric conditions for accurate photolysis rate calculations at the surface.

The MOCAGE assimilation system in its MACC configuration produces robust analyses for both O<sub>3</sub> and NO<sub>2</sub> as illustrated in the annual re-analysis reports <sup>2</sup>

### 3.2.7. SILAM

SILAM is a meso-to-global-scale dispersion model (Sofiev et al., 2008) that is used for atmospheric composition, emergencies, composition–climate interactions, and air quality modeling purposes. The model has been applied with resolutions ranging from 1km up to 3°, incorporates eight chemical and physical transformation modules and covers the troposphere and the stratosphere. The model is publicly available since 2007 and is used as an operational and research tool.

### 3.2.8. ENSEMBLE

To process the ensemble median, all seven individual models are first interpolated to a common 0.1°×0.1° horizontal grid. For each grid point, the ensemble model value is calculated as the median value of the individual model forecasts or analyses available. The median is defined as the value having 50% of individual models with higher values and 50% with lower values. This method is rather insensitive to outliers in the forecasts or analyses and is very efficient

---

<sup>2</sup><http://www.gmes-atmosphere.eu/documents/maccii/deliverables/eva/>

computationally. These properties are useful from an operational point of view. The method is also little sensitive if a particular model forecast or analysis is occasionally missing.

For the forecasts, the ENSEMBLE is produced for all levels and all species. For the analyses, the individual assimilation systems provide only analyses at the surface level and do not produce analyses for all species yet.
